(Received May 4, 2004; accepted in revised form June 14, 2005)

Abstract—The concentrations of P, V, Cr, Fe, Co, Ni, Cu, Ga, Ge, As, Mo, Ru, Rh, Pd, W, Re, Os, Ir, Pt, and Au in the group IVB iron meteorites Cape of Good Hope, Hoba, Skookum, Santa Clara, Tawallah Valley, Tlacotepec, and Warburton Range have been measured by laser ablation inductively coupled plasma mass spectrometry. The data were fitted to a model of fractional crystallization of the IVB parent body core, from which the composition of the parent melt and metal/melt distribution coefficients for each element in the system were determined, for a chosen value of D(Ni). Relative to Ni and chondritic abundances, the parent melt was enriched in refractory siderophiles, with greatest enrichment of $5\times$ chondritic in the most refractory elements, and was strongly volatile-depleted, down to 0.00014$/H_{11003}$ chondritic in Ge. Comparison to an equilibrium condensation sequence from a gas of solar composition indicates that no single temperature satisfactorily explains the volatility trend in the IVB parent melt; a small (<1%) complement of ultrarefractory components added to metal that is volatile-depleted but otherwise has nearly chondritic abundances (for Fe, Co and Ni) best explains the volatility trend. In addition to this volatility processing, which probably occurred in a nebular setting, there was substantial oxidation of the metal in the IVB parent body, leading to loss of Fe and other moderately siderophile elements such as Cr, Ga, and W, and producing the high Ni contents that are observed in the IVB irons. By assuming that the entire IVB parent body underwent a similar chemical history as its core, the composition of the silicate that is complementary to the IVB parent melt was also estimated, and appears to be similar to that of the angrite parent.

1. INTRODUCTION

It is believed that the magmatic iron meteorite groups represent fractionally crystallized cores of protoplanetary bodies that formed early in solar system history (Scott, 1972; Scott and Wasson, 1975; Haack and McCoy, 2003). Wasson (1995) estimated that there must be about 70 such differentiated parent bodies represented in the iron meteorite collections. Understanding the chemical and physical properties that produced the variations among the compositions and mineralogical features of iron meteorites, therefore, reveals something about the range of conditions in the solar nebula during the accretion and differentiation of their parent bodies.

This study focuses on the group IVB iron meteorites because, among the major magmatic iron groups, the IVBs have the most extreme compositions in a number of aspects, including the lowest abundances of the volatile elements Ga and Ge and, on average, the highest abundances of refractory siderophile elements such as Ir. In some regards the processes that governed the protoplanetary core compositions were acting to an extreme degree in the case of the IVBs, and therefore this group should provide a clear record of those processes.

There are two, very different, perspectives on the origin of the IVB irons. The most widely held view, that they reflect material that condensed at high temperatures in the solar nebula, has been mentioned by several authors (Anders, 1964; Scott, 1972; Haack and McCoy, 2003) but was argued most forcefully by Kelly and Larimer (1977). In the simplest form of this model, the IVB parent body would have been composed principally of high-temperature condensates, probably incorporating material from only the first <10% of the condensible material in the nebula (Kelly and Larimer, 1977). Based on a more comprehensive trace element study of the IVB irons, Rasmussen et al. (1984) proposed that the elevated Ni content resulted from oxidation of Fe in the parent body, and furthermore, that the elevated Ir/Ni ratio resulted from oxidation even of Ni, indicating a very high oxidation state. The volatile depletion in IVB irons was considered by Rasmussen et al. (1984) to be the product of parent body outgassing; in their view nebular processing played no detectable role in the formation of IVB irons.

The present study seeks to find some resolution between these two opposing hypotheses by expanding the number of elements for which compositions are known in a significant number of the IVB iron meteorites. Particularly important to this task is the abundance of Pd, which can be a sensitive indicator of the chemical processes affecting trace element compositions in metal (Campbell et al., 2001). The data are interpreted in terms of a fractional crystallization model of the IVB parent body’s core, and the chemical evolution of the IVB core is interpreted from the calculated parent melt.

2. EXPERIMENTAL

The IVB iron meteorites used in this study were: Cape of Good Hope (FMNH #ME29); Hoba (USNM #5606 and FMNH #ME2477); Skookum (AMNH #273-1; labeled as Klondike (Skookum Gulch)); Santa Clara (FMNH #ME2859); Tawallah Valley (FMNH #ME2705); Tlacotepec (FMNH #ME2159); and Warburton Range (AMNH #4229-1). Polished surfaces were analyzed for major and trace element analysis by laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). The laser ablation system utilized a CETAC LSX-200 laser...

3. RESULTS

3.1. LA-ICP-MS Data

The data for the seven meteorites studied are listed in Table 2. The precision is generally better than 4%, but analyses of elements having low abundance (e.g., Ga, Ge, As) and/or high backgrounds (e.g., P, V, Cr) sometimes show poorer precisions. The only datum below the detection limit was the measurement of As in Cape of Good Hope (Table 2). The entries for Hoba are the means from the two specimens.

The elemental concentrations for each meteorite, normalized to Ni and Cl chondrite abundances (Anders and Grevesse, 1989), are plotted in Figure 1 in order of each element’s volatility in a gas of solar composition (Kelly and Larimer, 1977; Wai and Wasson, 1979). The IVB irons are enriched in the refractory siderophile elements (Re, Os, W, Ir, Ru, Mo, Pt, and Rh) by factors ranging from (X/Ni)CI to Ni and Cl chondrite abundances (Anders and Grevesse, 1989).

depleted relative to Ni by a factor of ~0.3, and the normalized abundances of more volatile elements are progressively lower, reaching ~10^{-4} in the case of Ge (Fig. 1).

Customarily, trace element abundances in iron meteorites have been plotted against Ni content for purposes of classification and to identify diagnostic interelement trends, particularly fractional crystallization trends (Scott, 1972; Scott and Wasson, 1975). A weakness of this practice is that Ni varies little within a magmatic group, so even modest imprecisions in Ni abundance lead to substantial scatter in X-Ni plots. Several iron meteorite researchers (Haack and Scott, 1993; Wasson, 1999; Wasson and Richardson, 2001; Haack and McCoy, 2003) now advocate the use of Au and/or As to visualize interelement trends in iron meteorites, because these two elements partition more strongly than Ni, producing a wider abundance range within the fractional crystallization process. Following this recommendation, the new LA-ICP-MS data from this study are plotted against Au in Figure 2.

Most trace elements form well-defined trends with respect to Au among the IVB iron meteorites (Fig. 2). In addition, a plot of Re, Os, and Pt vs. Ir demonstrates that there are excellent correlations among the refractory PGEs (Fig. 3). The data, like those of Rasmussen et al. (1984), indicate that all of the IVB iron meteorites are distributed along compositional trends reminiscent of a fractional crystallization process; the suggestion of Larimer and Rambaldi (1978), that the IVBs should be considered as two genetically distinct subgroups, is not supported by our results.

3.2. Comparison to Literature Data

The data from the present study are compared to the neutron activation analysis (NAA) data of Rasmussen et al. (1984) in Figure 2. The LA-ICP-MS data exhibit a slightly larger spread in Au (59 to 174 ppb) than the NAA data do (62 to 166 ppb), but no systematic offset between the two sets of Au measurements is apparent. The agreement is similarly good between the Rasmussen et al. (1984) results and the LA-ICP-MS data for Cr, Co, Ni, and As, but minor differences between the data sets can be observed in Ga, Ge, W, Re, and Ir (Fig. 2). The most significant of these discrepancies is in the Ir data, which are ~29% higher, on average, in the present study than in Rasmussen et al. (1984). This is unexpected because Ir is one of the best-determined trace elements with either technique. The NAA data of Schaundy et al. (1972) are in better agreement, but still ~10% lower than the present results for Ir (Fig. 2). The Ir content of Filomena determined from the calibration data of the present study is 3.55 ± 0.15 ppm, only 5% higher than the 3.37 ppm value of Wasson et al. (1989).

The agreement between the present results for Pd in the IVB iron meteorites and those determined by thermal ionization mass spectrometry (Kaiser and Wasserburg, 1983; Chen and Wasserburg, 1990, 1996) is excellent, as shown in Figure 2. There are detectable differences between the LA-ICP-MS data and the TIMS data for Re and Os (Shen et al., 1996; Smoliar et al., 1996), however (Fig. 2). All three studies include measurements of Hoba, which was used as the standard for the LA-ICP-MS analyses. Our Re and Os values for Hoba are 9.5% and 2.3% higher, respectively, than those of Shen et al. (1996); for comparison, the Re and Os data of Smoliar et al. (1996) are lower than those of Shen et al. (1996) by 3.4% and 3.8%, respectively. These differences are small but significant, and suggest that interlaboratory comparisons between different TIMS laboratories may be similar to, or slightly better than, comparisons between ICP-MS data and TIMS data.

Also included in Figure 2 are data from an array of earlier sources using various techniques (Goldberg et al., 1951; Lövinger et al., 1957; Wetherill, 1964; Nichiporuk and Brown, 1965; Smales et al., 1967; Herpers et al., 1969; Moore et al., 1969; Schaundy et al., 1972; Buchwald, 1975). The data of Goldberg et al. (1951), Wetherill (1964), and Smales et al. (1967) agree particularly well with the LA-ICP-MS results. The spectrographic data of Nichiporuk and Brown (1965) give uniformly low values for Ru, Rh, Pd, Ir, and Pt.

In general, the results of the present study agree very well with those of earlier analyses, namely, that the IVB iron meteorites are enriched in refractory siderophile elements and strongly depleted in volatile siderophile elements. As Figure 2 indicates, there are a number of elements (e.g., V, Cu, Mo, Ru, Rh, and Pt) for which the present study has greatly expanded and improved the available data set of IVB iron meteorite abundances. In this regard the new results offer the most complete characterization to date of the chemistry of this meteorite group.

4. DISCUSSION

4.1. Fractional Crystallization of the Group IVB Iron Meteorite Parent Body

The compositional variation between meteorites within several of the major iron meteorite groups (the so-called 'magmatic' groups) has long been successfully interpreted as the product of fractional crystallization from a molten metallic body, such as the core of a protoplanet (Scott, 1972; Scott and Wasson, 1975). Here we model the fractional crystallization of the measured IVB irons to derive the composition of their parental melt. The fractional crystallization process follows the Raleigh equation:
\[ C(x) = C_0(x)D(x)(1 - f)^{D(x)-1} \quad (1) \]

where \( C(x) \) is the molar concentration of element \( x \) in the solid, \( C_0 \) is the initial concentration in the melt, \( D(x) \) is the solid/melt molar distribution coefficient of element \( x \) (assumed constant here, as discussed below), and \( f \) is the fraction of melt that has crystallized (constant over all elements for each meteorite). In fitting the data to the set of Eqns. 1 for each element \( x \), there are strong tradeoffs between the parameters, and at least two constraints must be applied to the model to obtain a robust solution.
An estimate must be made of at least one elemental concentration of the first crystallizing solid, or equivalently of the parental melt. Furthermore, the D value of at least one element must be fixed, usually to a well-determined experimental value.

Solid/melt distribution coefficients in Fe-rich metallic systems are known to be sensitive to the composition of the melt, particularly its ‘nonmetal’ component such as its S or P content (Willis and Goldstein, 1982; Jones and Drake, 1983; Chabot et al., 2003). This sensitivity creates some difficulty when modeling fractional crystallization of systems in which the S content of the parental melt was very low (Willis and Goldstein, 1982; Jones and Drake, 1983; Rasmussen et al., 1984; Chabot, 2004); this is manifest in a low frequency of sulfide inclusions, and is believed to be associated with the observed strong depletion of volatile elements. Therefore the S content of the melt will not increase significantly during most of the crystallization, and changes of D(x) due to S content of the melt can be neglected. The few sulfide inclusions that are present in IVB irons may represent trapped melt. Alternatively, up to 0.2 at% S is soluble in Fe metal, and some of the sulfide may be subsolidus precipitation. Regardless, the sulfide content is small, usually estimated on the order of 1 wt% or less (Willis and Goldstein, 1982; Rasmussen et al., 1984; Chabot, 2004).

As discussed below, most trace elements have distribution coefficients in this system that are close to one, and therefore their concentrations in the metal and the melt will not be greatly different. Therefore, the addition of ~1% melt to the metal will not strongly impact the interpretation of the trace element compositions.

However, the P content of the IVB system is larger than that of S, and the possible effect of P on the relevant melting relations and partitioning has not been carefully discussed previously. The measured P contents of the IVB iron meteorites range from 0.04 to 0.20 wt% (Table 2); these measurements include not only the P that is still dissolved in the metal, but also the numerous small phosphide precipitates that are distributed throughout the IVB irons (Buchwald, 1975). Using the partitioning coefficients for P of Willis and Goldstein (1982), the P contents of the IVB irons implies a range of 0.5 to 2.1 wt% P in their coexisting liquid. According to the parameterization of Chabot and Drake (2000), this variation in P content of the melt produces changes of only ±6% in D(Re) and D(Os), and no variation in D(Pd). This degree of composition dependence of D(x) is not considered to be important, and is therefore not included in the modeling below. Furthermore, the variation in Ni content is also small (Table 2), and its effect on D(x) is likewise negligible over the observed range (Willis and Goldstein, 1982). Therefore the assumption used here, that D(x) is constant and independent of f, is well justified (Rasmussen et al., 1984).

It can be shown that the slope of an interelement log-log plot is related to the D values of any two elements that are covarying in a fractional crystallization process, where Ds are constant:

\[ \log(C(x)) = \left(D(x) - 1\right)/\left(D(y) - 1\right) \times \log(C(y)) + b \]  

where b is also a constant (Scott, 1972). Therefore, one needs only to specify the D(x) for a single element x and the Ds for all other elements y are constrained by the manner in which the elements covary (e.g., Fig. 2). In most earlier interpretations of iron meteorite crystallization, the practice has been to constrain D(Ni) and determine other D(y) from log(Ni)-log(y) plots. Based on experimental studies demonstrating the slight incompatibility of Ni, commonly used values for D(Ni) range from 0.9 to 0.95, depending on the assumed S and Ni content. However, it can be seen from Eqn. 2 that the near-unity of D(Ni) implies that small inaccuracies in the D(Ni) value used will propagate into large inaccuracies in D(Ni)-1, and hence in D(y) for other elements. To overcome this problem we have chosen instead to use the experimentally determined value of D(P) as a constraint to the fractional crystallization model of IVB irons. Phosphorus is a minor element in iron meteorites, but is of sufficiently high abundance that precise D(P) data are available at appropriate P contents (Willis and Goldstein, 1982). Phosphorus is a highly incompatible element, with D(P) = 0.995 ± 0.003 for compositions appropriate to the IVB irons (Willis and Goldstein, 1982), and therefore the model is insensitive to modest inaccuracies in the experimentally derived D(P) value. For example, a 1% error in D(P) corresponds to only a 1% error in D(y)-1. As shown in Figure 4, the chosen value of D(P), combined with the observed variation between P and Ni in the IVB irons, indicates a value of D(Ni) = 0.924 ± 0.015. This value is lower than D(Ni) = 0.95 used by Rasmussen et al. (1984), based on an extrapolation of Willis and Goldstein’s (1982) data, but it is consistent within the uncertainties of that study. For further comparison, the distribution coefficient that can be calculated from the thermodynamic analysis of the Fe-Ni system by Chuang et al. (1986) is D(Ni) = 0.904 ± 0.003 over the range of IVB iron meteorite compositions in Table 2.
We follow the example of Rasmussen et al. (1984) and assume that the initial Ni content of the first crystallizing solid is slightly less than the lowest Ni content observed among the IVB irons. This is equivalent to the assumption that the observed range of compositions in the IVB irons is suitably representative of the core that they sample, and that there is no strong sampling bias. Specifically, we choose a value of 15.5 wt% Ni, which will yield a range of $f$ values between 0.16 and 0.86 for the IVB irons. To test the sensitivity of our model results to this assumption, we also consider an extreme case in which 14.9 wt% Ni, yielding $f = 0.5$ for all meteorites (Fig. 5b); in this model the IVB irons would be strongly biased toward the later stages of the fractional crystallization process.

Having justified the assumptions of constant $D(x)$, $D(P) = 0.095$, and $C_{\text{initial}}(\text{Ni}) = 15.5$ wt% as discussed above, the measured compositions of IVB iron meteorites in Table 2 were fit to the set of Eqs. 1 by the weighted least-squares method; the results are given in Tables 3 and 4. Vanadium was not modeled, because of the relatively large scatter in those data (Fig. 2). As mentioned earlier, the modeled values of $f$ range between 0.16 and 0.86, indicating an adequate sample of the fractional crystallization process. The sensitivity of the model to the assumed $C_{\text{initial}}(\text{Ni})$ is demonstrated in Figure 6, in which the Ni- and chondrite-normalized composition of the parent melt from the preferred model ($C_{\text{initial}}(\text{Ni}) = 15.5$ wt%) is compared to the model of strongly biased sampling ($C_{\text{initial}}(\text{Ni}) = 14.9$ wt%) introduced in Figure 5b. For most elements the difference between the two models is negligibly small, and in general the assumed $C_{\text{initial}}(\text{Ni})$ has no significant impact on the conclusions of the discussion below. A second, extreme case ($C_{\text{initial}}(\text{Ni}) = 15.7$ wt%), producing $f = 0.00$ for the earliest-crystallizing sample, is also shown in Figure 6, and is hardly distinguishable from our preferred model.

As shown in Figure 2, the current data set is largely compatible with the earlier NAA data of Rasmussen et al. (1984), and this extends to the fractional crystallization models as well. The differences in partition coefficients derived in the present study from those of Rasmussen et al. (1984), which are also given in Table 3, arise principally from the applied experimental constraints on $D(x)$. Rasmussen et al. (1984) chose $D(\text{Ni}) = 0.95$ in their modeling of the fractional crystallization of the IVB irons, but for reasons given above we chose $D(P) = 0.095$, from which the multielement fit produced $D(\text{Ni}) = 0.924$ (Table 3). The two sets of partition coefficients are found to be in excellent agreement if those of Rasmussen et al. (1984) are recalculated using $D(\text{Ni}) = 0.924$. Our modeled $f$ values (Table 4) also agree approximately with those of Rasmussen et al.
(1984), a consequence of constraining the Ni content of the first-crystallizing solid in a similar manner to that earlier work.

The modeled distribution coefficients are a relatively precise, internally consistent data set that can be usefully compared to experimentally derived values of $D(x)$ for S-free systems. Experimental partitioning data in metal-melt systems have been compiled and fit to functions of the nonmetal content of the melt by Jones and Malvin (1990) and by Chabot and Jones (2003). Jones and Malvin (1990) presented two different fits for S-rich melts and for P-rich melts, which do not always precisely converge at S- and P-free compositions. Calculated $D(x)$ from each of these parameterizations of the experimental data are listed in Table 3 for the composition 0 wt% S, 1.3 wt% P appropriate to the IVB parent melt (the P content used here is an average of the IVB group); for Cu no published parameterization is available, so a fit to the data from Chabot et al. (2003) was used. In most cases the agreement is excellent, well within the scatter of the experimental data, hence the quality of the fits.

A notable exception is Cr, which is distinctly compatible in the IVB meteorites (see Figure 2, where Cr is inversely correlated with the incompatible element Au) but is incompatible in laboratory experiments and in the parameterization of Jones and Malvin (1990). Chabot and Jones (2003) discussed the weakness of such parameterizations in application to chalcophile elements, specifically Ag, Cu, and Cr; the extension of these parameterizations to the low S contents suitable to the IVB irons may therefore be unreliable. We note that Rasmussen et al. (1984) also determined Cr to behave compatibly during crystallization of the IVB parent melt (Fig. 2; Table 3). In fact, negative Cr-Ni correlations suggest that Cr could have been a compatible element during crystallization of other magmatic

Fig. 6. Siderophile element abundances in the parent melt of the IVB iron meteorites, determined from fractional crystallization modeling of the LA-ICP-MS data. Abundances are normalized to Ni and CI chondrites (Anders and Grevesse, 1989), and ordered according to their volatility. Modest differences are observed between the preferred model (heavy line: $C_{\text{initial}}(\text{Ni}) = 15.5$ wt%), the model biased toward $f \geq 0.50$ introduced in Figure 5 (thin line: $C_{\text{initial}}(\text{Ni}) = 14.9$ wt%), and a limiting case producing $f \geq 0.00$ for the earliest-crystallizing IVB iron (dotted line: $C_{\text{initial}}(\text{Ni}) = 15.7$ wt%).
iron meteorite groups, such as IIAB, IIIAB, and IVA (Scott, 1972); if this is correct, it contradicts the experimental data for Cr in S-bearing metallic systems. However, it is also conceivable that the correlations in the latter three groups derive from D(Cr) values that are less than one, but that vary greatly with increasing S content of the melt during crystallization of those iron meteorite systems, as shown for the modeling of Cu in the IIIAB group (Hongsresawat et al., 2002).

The results of the fractional crystallization modeling (Fig. 6) show that the parent melt had a CI chondrite-normalized composition that was largely a function of volatility of the elements. The most refractory elements were enriched in the IVB parent melt by a factor of ~5 relative to Ni, and this enrichment factor decreases gradually with diminishing condensation temperature. At volatilities lower than Ni, the normalized abundances drop off more rapidly, and the most volatile siderophile elements were present in the parent melt at or below ~0.001 times chondritic levels. Superimposed upon this pronounced volatility trend are notable depletions, particularly in the moderately siderophile elements such as Fe, W, and Cr. These depletions signal redox processes as important contributors, in addition to volatilization, to the parent melt composition for the IVB irons.

4.2. Oxidation of the IVB Parent Melt

The degree of oxidation that the IVB parental melt experienced prior to crystallization can be calculated from the depletions in moderately siderophile elements relative to highly siderophile elements that have similar volatilities. In particular, much can be learned from considering the relative abundances of Ni, Co, Fe, and Pd shown in Figure 6. First, note that the CI-normalized Fe/Pd ratio in the IVB parent melt was \((\text{Fe/Pd})_{\text{CI}} = 0.28\). Calculations of equilibrium condensation of metal from a gas of solar composition have shown that Fe and Pd have very similar volatilities, and therefore that condensation/ evaporation processes should not strongly fractionate Fe from Pd (Kelly and Larimer, 1977; Campbell et al., 2001). However, Pd is much more strongly siderophile than Fe, and we interpret the observed Fe/Pd depletions as a consequence of oxidation of the IVB parent melt. Moreover, \((\text{Ni/Pd})_{\text{CI}} = 1.0\) in the inferred parent melt, and Fe/Ni is depleted relative to chondritic abundances to a degree similar to Fe/Pd. This implies that the Fe/Ni ratios, and high Ni contents, of the IVB irons was produced by oxidative loss of Fe prior to their fractional crystallization, as previously stated by Rasmussen et al. (1984), and not by incomplete condensation of the metal, as had been advocated by Kelly and Larimer (1977).

However, the oxidation responsible for the Fe/Pd and Fe/Ni depletions was not severe enough to cause also a Ni depletion, as had been proposed by Rasmussen et al. (1984). If it had been, then the Ni/Pd ratio would not be chondritic, because Pd is more strongly siderophile than Ni. Furthermore, if the oxidation of the IVB precursor had been so extensive that Ni was significantly oxidized, then Co would be likewise depleted, to an intermediate degree between that of Fe and Ni; this is not observed (Fig. 6).

Rasmussen et al. (1984) appealed to oxidative loss of Ni from the metal to explain the fractionation between Ni and more highly siderophile elements, such as Ir, in the IVB irons. Because this mechanism is incompatible with the observed, chondritic Ni/Pd and Co/Ni ratios, we conclude that the fractionation between Ni and highly refractory siderophiles (Re, Os, Ir, Ru, Pt; Fig. 6) is a consequence of the relative volatilities of these elements, as suggested by Anders (1964), Scott (1972), and Kelly and Larimer (1977). These fractionations will be considered further in the following section.

The oxidation state associated with the observed Fe depletion from the IVB metal can be quantified if the silicate composition that equilibrated with the metal melt is estimated. In Section 4.4 below we make such an estimate, based principally on the assumption that the bulk IVB parent body had a slightly refractory-enriched, devolatilized chondritic composition, and the silicate is complementary to the metal. Anticipating the silicate composition calculated in Section 4.4, we can determine the oxygen fugacity at which the IVB parent melt equilibrated with silicate from

\[
\Delta IW = 2 \log \left( \frac{a_{\text{FeO}}}{a_{\text{Fe}}} \right) \tag{3}
\]

where \(\Delta IW\) is the difference in log units between the \(f(O_2)\) and the iron-wustite buffer, \(a_{\text{FeO}}\) is the activity of FeO in the silicate, and \(a_{\text{Fe}}\) is the activity of Fe in the metal. Using the thermodynamic data of Chase (1998) and making the approximation of ideal solution in both silicate and metal, we find that metal-silicate equilibrium occurred at \(\Delta IW \approx -1\).

Teshima and Larimer (1983) considered the presence of trace amounts of chromite and daubreelite in Santa Clara and Warburton Range, and its implication on the \(f(O_2)\) and \(f(S_2)\) conditions of the IVB parent body. They qualitatively conclude that the IVB parent body was more reducing than most other parent bodies, with the exception of that of the enstatite chondrites. This conclusion appears to be contradicted by the present results, but it is important to recognize that the chromite and daubreelite likely record the conditions during low temperature, subsolidus exsolution. In contrast, the bulk composition of the IVB iron parental melt reflects the conditions during segregation of the metal and silicate phases, which presumably occurred in the molten or partially molten state.

The temperature at which the metal and silicate effectively equilibrated can be estimated from the metal phase equilibria. The fact that the IVB irons are successfully described by fractional crystallization from a S-free melt, as discussed in Section 4.1, suggests that the metal attained a temperature of at least 1760 K; the liquidus in the Fe-Ni system at 15.5 wt% Ni (Chuang et al., 1986) is 1766 K, and examination of the Fe-P and Ni-P binaries (Massalski et al., 1990) suggests that the effect of 0.4 wt% P in the initial melt would have lowered the liquidus by \(~5\) K. The last of the IVB irons to crystallize was Warburton Range, at 18.0 wt% Ni. In the Fe-Ni system this composition crystallizes at \(~1758\) K, but the higher P content of \(~2\) wt% in the melt at this stage would have depressed the liquidus by \(~60\) K. Therefore crystallization of the IVB irons was mostly completed from 1760 K to 1700 K, though trace amounts of melt could have persisted in the Ni-P binary at 1143 K (Doan and Goldstein, 1970; Massalski et al., 1990). At these high temperatures the silicate portion of the IVB parent body would also have been mostly molten, and one can conclude that metal and silicate segregated and equilibrated within an almost completely molten parent body.

From 1760 K to 1700 K the Mo-MoO\(_2\) oxygen fugacity

\[
f^{(\text{O}_2)} = 10^{-a IW} \tag{4}
\]
strong dependence on volatility (Fig. 6). The elements are
concentrations of the IVB iron meteorite parent melt show a very
4.3. Nebular Fractionations Affecting the IVB
parent body had occurred at lower temperatures (<1200
K, for example), then one would expect to see larger depletions
in W and Mo than are observed in the IVB irons. The observed
Cr-Cr2O3 buffer is stronger than the Fe/Pd fractionation—
Fig. 6—is also consistent with an f(O2) of IW-1 during
deposited metal-silicate segregation on the IVB parent body, because
the Cr-Cr2O3 buffer is ~4.0 log units below IW at 1760 K to 1700 K.

4.3. Nebular Fractionations Affecting the IVB Parent Melt

In addition to the important effect of oxidation discussed in
the previous section, the calculated siderophile element concen-
trations of the IVB iron meteorite parent melt show a very
strong dependence on volatility (Fig. 6). The elements are
ordered in Figure 6 by decreasing condensation temperature
(Tc) into a single-phase Fe,Ni alloy from a gas of solar com-
position at 10 Pa (Palme and Wlotzka, 1976; Kelly and La-
rimer, 1977; Wai and Wasson, 1979; Sylvester et al., 1990;
Campbell et al., 2001, 2003). The most refractory siderophile
elements, Re and Os, are enriched relative to Ni and CI chon-
drites (Anders and Grevesse, 1989) in the preferred estimate of
the IVB parent melt composition by a factor of 5.1. With
decreasing condensation temperature the other refractory side-
rohile elements are less enriched, and Co and Pd are at
chondritic abundances relative to Ni. Elements having Tc be-
low that of Fe are increasingly depleted, by orders of magni-
tude, and the most volatile siderophile measured, Ge, was
depleted at a level of (Ge/Ni)1.3 = 1.4 × 10^-4. Apart from the
redox-induced depletions in W, Fe, and Cr discussed above, the
volatility trend shown in Figure 6 is mostly monotonic. An
exception is the subchondritic Cu/Ga ratio that is not expected
on the basis of the condensation calculations (Wai and Wasson,
1979), but this may be excused because of the uncertainty in
activity coefficients used for these elements in the solid Fe-Ni
alloy. Alternatively, chalcophile Cu may be sequestered in the
rare trolilites in IVB irons.

The slope in normalized abundance that is observed among
the refractory siderophiles in the IVB iron meteorites (Fig. 1)
and their calculated parent melt (Fig. 6) is significant. These
elements (Re, Os, Ir, Ru, Pt) are so refractory that they should
be completely condensed at temperatures low enough for Fe
and Ni to dominate the metallic phase. Under such circum-
stances one would expect that their relative abundances would
be chondritic, not sloping with volatility as observed. Similar
refractory siderophile element patterns in Ca,Al-rich refractory
inclusions (CAIs) led Palme et al. (1994) and Campbell et al.
(2003) to conclude that these objects contained multiple
sources of refractory metal, each reflecting a different high-
temperature history or characteristic temperature of formation.
No single temperature, according to equilibrium calculations of
alloy condensation from the solar nebula, can account for the
gently sloping patterns; instead, at each specific condensation
temperature the relative abundances among these elements tend
to be stepped (Palme et al., 1994; Campbell et al., 2003).
Furthermore, at temperatures high enough that fractionations
appear among the refractory PGEs, the PGE contents of the
alloy are extremely high, up to 10^5 times higher than in the IVB
iron meteorites. Consequently, we interpret the sloping, moder-
ately enriched refractory siderophile abundances shown in
Figures 2 and 6 as indicating the presence of a very small
amount of high-temperature metal. Many such grains are likely
to have been incorporated into the IVB parent body, and the
superposition of them all produced the observed abundance pattern. Depending on the particular composition of the refrac-
tory precursor metal grains, they could have composed even
less than 0.01 wt% of the total metal. The balance of the IVB
parent body, in this scenario, could have consisted of volatile-
depleted but otherwise approximately chondritic composition.

The relative abundances of refractory siderophile elements in
the IVB parent melt thus leads to the conclusion that for these
elements, at least, it was nebular processing that controlled
their composition. No parent body process could reasonably be
expected to produce this smoothly varying pattern reflecting
very high temperature volatilization (Fig. 6). The devolatiliza-
tion of the parent melt is a different matter. There are no
features in the trace element pattern that explicitly exclude the
possibility of devolatilization as a consequence of parent body
gassing (Rasmussen et al., 1984). However, the volatile
element depletions are quite strong, and it may be difficult to
devolatilize an entire parent body to this level of efficiency.
Furthermore, it is not necessary to invoke this process, because
the refractory siderophiles require that nebular processes are
preserved in the chemistry of the IVB iron meteorite compos-
sitions, and therefore volatile loss can simply be interpreted as
a natural consequence of these high-temperature nebular pro-
cesses (see Humayun and Cassen, 2000, for a discussion). It
should be noted that existing models of nebular volatile ele-
ment depletion (Humayun and Cassen, 2000) cannot explain
the extent of depletion observed for the most volatile-element
depleted bodies, such as the Earth, Moon, eucrite parent body
and angrite parent body.

Haack and McCoy (2003) have implied a possible genetic
relationship between the IVB irons and condensate metal in
CH/CB chondrites. The PGE/Ni ratios in CH/CB metal grains
(e.g., Campbell et al., 2001) are not elevated like those of the
IVB parent melt (Fig. 6), and as Haack and McCoy (2003) note,
the nebular temperatures required to generate the IVB parent
melt composition are correspondingly higher than for the
CH/CB metal. The hypothesis of a relationship between these
two meteorite groups is neither strengthened nor negated by our
results.

4.4. Silicate Portion of the IVB Parent Body

It is reasonable to suppose that the silicate portion of the IVB
parent body experienced a similar chemical history to that of
the core. Namely, it is likely that most of the complementary
IVB silicate component had moderate refractory enrichments,
strong volatile depletions, and a redox state that is similar to
that recorded in the IVB iron meteorites. Therefore some pre-
dictions can be made regarding the composition and differen-
tiation of the IVB silicate components.
In Section 4.2 it was determined that the metallic melt from which the IVB iron meteorites crystallized must have experienced at least 1760 K. At this temperature the silicate portion of the parent body would also have been extensively molten, and it is reasonable to infer that metal/silicate segregation into a core and mantle was highly efficient in this mostly molten state. If samples of the silicate fraction of the IVB parent body exist in the meteorite collections, they would be classified as achondrites and would have a very low metal content reflecting this efficient liquid metal/liquid silicate separation.

We estimate the composition of the IVB parent body silicate as a chondritic composition modified by refractory element enrichment, strong volatile element depletion, and extraction of metal having the composition of the IVB iron meteorite parent melt. The results of such a calculation, using CI chondrites as the reference chondritic composition, are displayed in Figure 7. In this calculation the refractory lithophiles Ca, Al, and Ti were enriched by a factor of 4 relative to Mg and chondritic abundances, based on the range of refractory siderophile element enrichments observed in the IVB irons (Fig. 6). Other refractory lithophiles (Sc, Y, REEs) are expected to have been similarly enriched. Depletions of volatile lithophiles such as Cr, Mn, Na, and K were estimated from the range of depletions of volatile siderophiles in the IVB irons (Fig. 6). The bulk silicate composition resulting from these estimates is also given in oxide wt% in Figure 7. Under the simplifying approximation that the activity of FeO in the silicate is adequately represented by its mole fraction \((X_{FeO} = 0.20)\), the oxygen fugacity can be calculated from Eqn. 3 as approximately \(IW - 1\), which was anticipated in section 4.2 above.

Are there known achondrites having compositions that are compatible with this estimate of the IVB parent body silicate portion? Comparisons of this nature are severely compromised by the fact that the meteorite samples are pieces of silicate bodies that may have been differentiated in complex manners that obscure the bulk parent body compositions. Nevertheless, there is at least one achondrite group that suggests itself as a possible silicate complement to the IVB iron meteorites; this is the angrites. Just as the IVB iron meteorites have the lowest volatile siderophile element contents of any iron meteorite group, the angrites are noted for having lower concentrations of alkalis and other volatile lithophiles than any other basaltic meteorites (Mittlefehldt et al., 1998). Although the petrogenesis of angrites is generally not well understood, one model for their formation invokes a bulk silicate composition of the angrite parent body that is strikingly similar to that estimated above for the IVB parent body. Longhi (1999) parameterized experimental studies of the CMAS + Fe system to evaluate the liquidus phase relations that should be relevant to angrite genesis. He found that the parental source that best explains the range of angrite compositions can be described as an alkali-depleted primitive chondrite (CV) composition, to which a refractory component similar to Ca,Al-rich inclusions has been added, and from which a fraction of approximately 0.4 of the total Fe has been sequestered as metal (Longhi, 1999). The angrite parent body core corresponding to such a model would thus be a volatile siderophile-depleted, refractory siderophile-enriched metal from which \(\sim 0.6\) of the Fe is lost to oxidation into the silicate, very similar to the description of IVB metal presented above, where 0.72 of the Fe is lost by oxidation. In Figure 7 some angrite whole rock abundances and a composition corresponding to Longhi’s (1999) angrite parent body model are compared to our estimate of the IVB parent body silicate. (The potassium depletion for the body is calculated from the K/Ba ratio of Angra dos Reis; Humayun and Clayton, 1995.) In detail, there are some differences between the two models, notably the degree of Fe reduction and the nature of the refractory component that is added. Furthermore, the oxidation state under which the angrite silicates last equilibrated (IW + 1 to IW + 2; Mittlefehldt et al., 1998) is higher than that indicated for metal/silicate segregation by the scenarios presented here and by Longhi (1999). Nevertheless, within the known meteorite collection the angrites are the best available candidates to be representatives of the silicate portion of the IVB parent body. A strong test that could possibly exclude (but not confirm) this association would be a comparison of oxygen isotope compositions of the two meteorite groups. However, no oxygen isotope data are available for the IVB iron meteorites because oxygen-bearing inclusions in them are vanishingly rare (Teshima and Larimer, 1983).

5. CONCLUSIONS

The use of LA-ICP-MS to perform bulk analyses has improved the understanding of group IVB iron meteorite formation by significantly expanding the number of trace elements...
for which these meteorites have been analyzed in a systematic manner. The precision of these measurements is commonly <10% even for volatile siderophile elements such as Ga, Ge, and Au that are at low abundances (50–200 ppb) in these meteorites. A model of the fractional crystallization of the IVB parental melt has been presented that generated the initial concentrations and metal/melt partition coefficients for siderophile trace elements in that crystallizing system. The partition coefficients derived are very consistent with experimentally-constrained values for S-free metallic systems, with the exception of D(Cr) highlighting the need for further systematic experimental study of chalcophile element partitioning in these systems.

Based on the results of this study, the following sequence of events is proposed to have produced the IVB iron meteorites:

1. High temperature volatilization/condensation processes in the solar nebula caused fractionations among highly refractory siderophile elements (Mo, Ru, Rh, W, Re, Os, Ir, Pt) in numerous metal grains. These grains represented a range of equilibration temperatures, and may have been highly PGE-rich and Fe-Ni-poor.

2. The refractory metal was accreted into the IVB parent body, along with Fe-Ni metal in which the refractory siderophiles need not have been fractionated from one another, and perhaps not even enriched relative to Fe and Ni. The Fe-Ni metal was, however, probably volatile-depleted prior to parent body accretion. If the refractory metal component was sufficiently PGE-rich, it may have been only a small fraction, even <0.01 wt%, of the total metal.

3. The IVB parent body achieved very high internal temperatures of 1760 K or greater. During melting, coalescence, and homogenization of metal in the parent body, the various metal sources were blended, producing a sloped refractory siderophile element pattern in which abundance was a function of volatility, for example (Os/Ni)C1 = 5 and (Pt/Ni)C1 = 2. Volatile siderophiles were strongly depleted in the metallic melt, with (Ge/Ni)C1 = 10^{-4}.

4. The oxygen fugacity during the melting and metal/silicate segregation in the IVB parent body was approximately IW-1, causing several redox-sensitive elements to partition into the silicate. The observed depletions relative to elements of similar volatility, (Cr/Au)C1 < (Fe/Pd)C1 < (W/Os)C1 < (Mo/Ir)C1, is consistent with the relative positions of the metal-oxide buffers of these elements at high temperatures. The oxidative loss of Fe from the metal was responsible for the observed high Ni contents of the IVB iron meteorites.

5. Fractional crystallization of the melt occurred in the IVB core, mostly over the temperature range ~1760 K to ~1700 K, and produced the compositional range that is still preserved in the IVB iron meteorites. The melt was virtually S-free but contained a modest P content (0.4 wt% initially), which had only a very small effect on the trace element partitioning. The silicate portion of the IVB parent body is presumed to have undergone a similar chemical history, and therefore should exhibit textures and compositions that reflect an extensively molten source that bore modest refractory enrichments, strong volatile depletions, and loss of approximately 28% of total Fe to the metal. Of the known achondrites, the angrites are the closest match to this postulated IVB silicate source, but this association remains speculative and merits further examination.

Acknowledgments—We are grateful to M. Wadhwa and C. Nuñez of the Field Museum of Natural History and D. Ebel and J. Boesenberg of the American Museum of Natural History for providing specimens of group IVB iron meteorites. We also benefited from discussions with N. Chabot. The paper benefited from reviews by N. Chabot, H. Haack, D. Mittlefehldt and an anonymous reviewer. This work was supported by the NASA Cosmochemistry Program through grant NAG5-13133 to M. H.
